The cross section of the $^{89}\text{Y}(p,\gamma)^{90}\text{Zr}$ reaction was determined at $E_p=1.4-4.8$ MeV via angle-integrated measurements carried out by means of a $4\pi$ NaI summing detector as well as via angular distribution measurements using an array of 4 HPGe detectors with 100% relative efficiency. The resulting cross sections vary from 0.5 to 5 mb. Astrophysical S factors and reaction rates have also been derived. A good agreement between the experimental rates and and the predictions of statistical theory has been found.
