Abstract

The longitudinal polarization of the stored electron beam in the *AmPS* ring will be measured through the laser Compton backscattering technique. With the outlined design the measurement of the expected 70% degree of polarization to a statistical precision of 3% requires less than 60 sec under ideal conditions.

1 Introduction

The continuous beam electron facilities, that are becoming operational worldwide, form an excellent tool for research in nuclear and hadronic physics with electromagnetic probes. The use of polarized electrons and polarized targets is considered an essential factor in their experimental programs [1].

A design for producing an intense stored beam of longitudinally polarized electrons at the Interaction Point (*IP*) of the existing Internal Target Hall (*ITH*) of the *MEA/AmPS* facility has been made by a collaboration between *NIKHEF* and the *BINP* and *ISP* Institutes from Novosibirsk. Technically the polarization project comprises of the construction of a polarized electron injector and a Siberian Snake to compensate the depolarization effects in the ring [2], [3]. A beam polarimeter, based on the laser Compton backscattering technique, has been designed and installed in the *AmPS* ring for measuring and monitoring continuously the longitudinal polarization of the stored electron beam.

[1] pesent address: IASA, Division of Accelerating Physics, P.O.Box 17214, 10024 Athens, Greece

The spin-dependent Compton scattering of circularly polarized photons off polarized electrons is currently used or planned as a fast, non-destructive, and accurate method for measuring the polarization of high-energy electron beams in storage rings at different laboratories [4].

In the following sections the physics of the Compton scattering is briefly discussed and the main features of the design of the laser Compton backscattering beam polarimeter for the $AmPS$ ring are presented.

2 The Physics of the Compton Scattering

The Compton effect involves the scattering of energetic photons off free (or quasi-free) electrons. If photons with energy E_λ in the LAB frame collide head-on with electrons of energy E_e and velocity β, the energy E_γ of the scattered photons is given by

$$E_\gamma = \frac{(1+\beta)E_\lambda}{1-\beta cos\theta_\gamma + \frac{E_\lambda}{E_e}(1+cos\theta_\gamma)} \tag{1}$$

where θ_γ is the angle of scattered photons with respect to the incident electrons. For high electron beam energies and for incoming photons with energy corresponding to typical laser systems the most energetic photons are emitted into a narrow cone centered on the direction of the incoming electron beam. The maximum energy of scattered photons, E_γ^{max}, occurs for $\theta_\gamma = 0^0$ independently of the energy of the incoming electron and photon beams.

In the LAB frame the differential cross section for Compton scattering of circularly polarized photons off longitudinally polarized electrons can be expressed as [5]

$$\frac{d\sigma}{dE_\gamma} = \frac{d\sigma_0}{dE_\gamma}[1 + S_3 P_Z \alpha_{3z}(E_\gamma)] \tag{2}$$

where $\frac{d\sigma_0}{dE_\gamma}$ is the differential cross section for unpolarized Compton scattering, P_Z is the degree of longitudinal polarization of the electron beam and S_3 is the Stokes parameter that defines the circular polarization of the incident photon beam; $S_3 = +1(-1)$ for completely left (right)-handed polarized photons. The quantity α_{3z} is the longitudinal analysing strength. The analysing strength depends on the energy of the electron and photon beams. For a given electron energy the shorter the laser wavelength the larger the analysing strength. In addition more energetic electron beams result in larger analysing strengths in polarized Compton scattering.

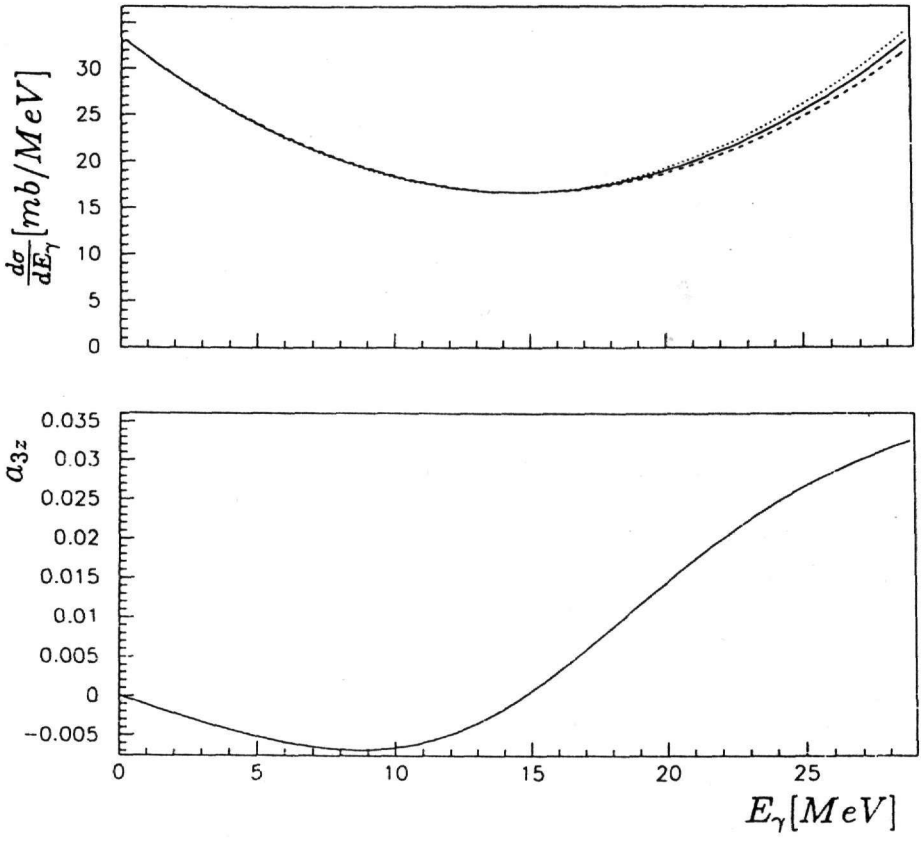

Fig. 1. *The energy spectra of backscattered photons (top) and the longitudinal analysing strength a_{3z} (bottom) in Compton scattering.*

The energy spectra and the longitudinal analysing strength in Compton scattering are presented in Figure 1 for an energy of $E_e = 900\ MeV$ and for laser photons with an energy of $E_\lambda = 2.41\ eV$ that corresponds to a wavelength of $\lambda = 514.5\ nm$. Solid lines in Figure 1(top) represent the unpolarized case. For comparison the energy spectra of the polarized Compton scattering are plotted for the cases of $S_3P_Z = +1$ (dotted lines) and $S_3P_Z = -1$ (dashed lines). In Figure 1(bottom) the quantity α_{3z} is plotted as a function of the energy of backscattered photons. Larger longitudinal analysing strengths correspond to backscattered photons with higher energies. The maximum value of the longitudinal analysing strength occurs for backscattered photons with energy E_γ^{max}.

3 The Measurement of the Longitudinal Polarization

If a circularly polarized photon beam is backscattered off the electron beam, the scattered intensity will depend on the helicity of the light and the electron spin according to the Compton cross section. By switching the helicity of the light and/or the electron the resulting asymmetries can provide a direct measurement of the electron beam polarization.

The experimental asymmetry in the counting rate for Compton scattering, A_C, is given by

$$A_C = \frac{N_R - N_L}{N_R + N_L - 2N_{bkgd}} \tag{3}$$

where N_R and N_L are the total number of backscattered photons normalized to the integrated beam current for right and left helicities of the incident photons respectively. N_{bkgd} represents the background contribution. The quantity A_C is related to the longitudinal electron polarization P_Z via the following relation

$$P_Z = \frac{A_C}{S_3 < a_{3z} >} \tag{4}$$

The average analysing strength $< \alpha_{3z} >$ is calculated in the kinematical region defined by the angular acceptance of the detector.

The total number of backscattered photons, N_γ, for right and left helicities of the initial photons, is related to the relative accuracy of the longitudinal asymmetry (polarization) $\frac{\Delta A_C}{A_C}\left(\frac{\Delta P_Z}{P_Z}\right)$ via

$$\frac{\Delta A_C}{A_C} = \frac{\Delta P_Z}{P_Z} = \sqrt{\frac{1 - A_C^2}{N_\gamma A_C^2}} \tag{5}$$

where the error of S_3 has been neglected.

The required total measuring acquisition time, $T(sec)$, as a function of the beam polarization P_Z for a given relative accuracy can be expressed as

$$T = \frac{N_\gamma}{\dot{N}_\gamma} = \frac{1 - (S_3 P_z < a_{3z} >)^2}{(S_3 P_z < a_{3z} >)^2 \left(\frac{\Delta P_Z}{P_Z}\right)^2 \dot{N}_\gamma} \tag{6}$$

where $\dot{N}_\gamma(Hz)$ is the count rate of backscattered Compton photons. In the case of continuous electron and laser beams the rate of backscattered Compton photons can be estimated from

$$\dot{N}_\gamma = 2\dot{N}_{ph} \frac{N_e}{C} \frac{L}{\Sigma} \sigma_{C0} \tag{7}$$

where, $\dot{N}_{ph}(photons/sec)$ is the initial photon flux, N_e is the number of electrons circulating in the ring, $C(m)$ is the circumference of the storage ring, $L(m)$ is the length of the Interaction Region (IR) of the electron beam with the laser light, $\Sigma(cm^2)$ is the larger of the transverse sizes of the electron and the laser beam, and $\sigma_{C0}(cm^2)$ is total the cross section for unpolarized Compton scattering.

4 The Beam Polarimeter of $AmPS$ ring

4.1 The layout

A schematic layout of the Compton polarimeter with its position in the $AmPS$ ring is shown in Figure 2 [6]. The polarimeter consists of the laser system with its associated optical system and a detector for the detection of backscattered photons. The straight section ($\sim$ 2.5 m) between the first two dipoles after the Internal Target Facility (ITF) has been chosen as the electron beam-laser light IR. The crossing angle between the laser and the electron beams should be as small as possible in order to maximize the luminosity of the interaction. Another criterion, for the choice of the IR, is that the backscattered photons should be separated from the large bremsstrahlung background coming out from the 32 m long $West$ straight section of $AmPS$. The backscattered photons leave the IR traveling in the same direction as the electrons of the beam and are separated after the second dipole.

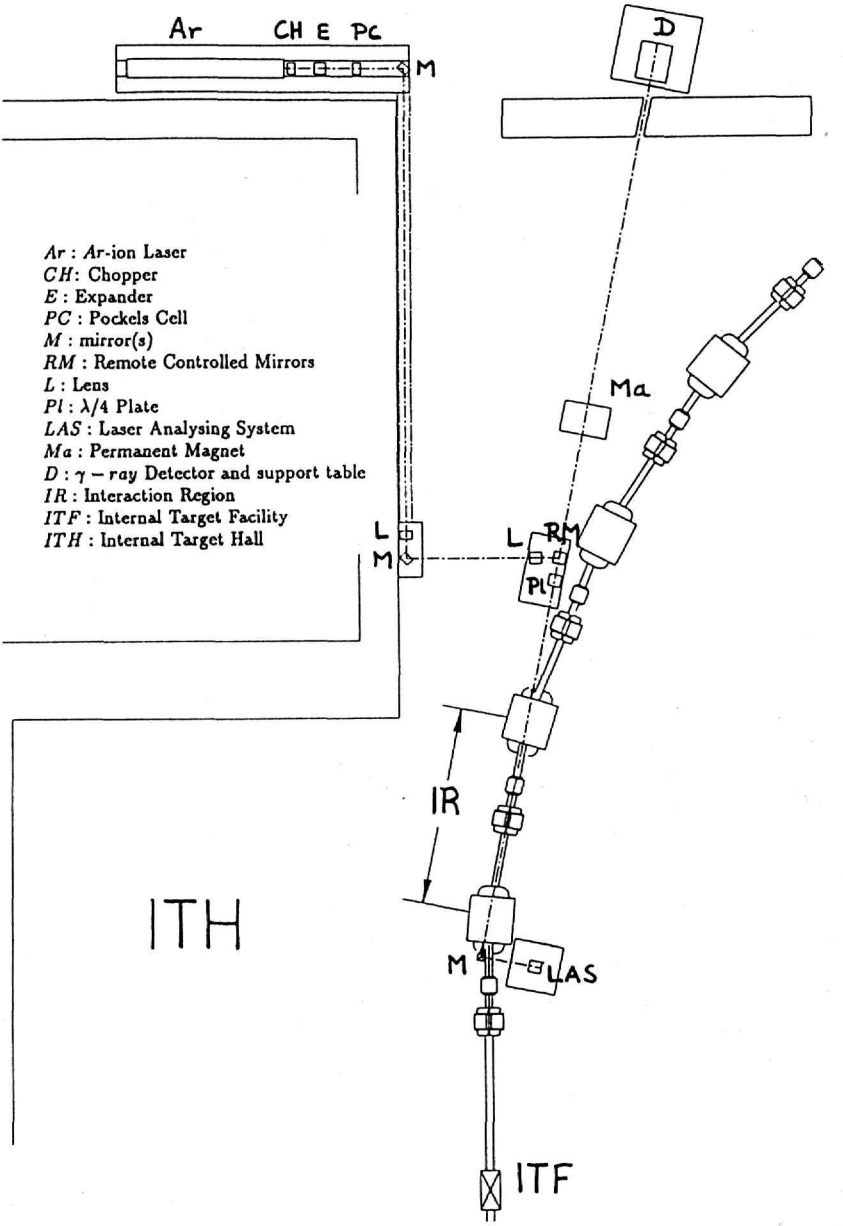

Fig. 2. *Schematic layout of the electron beam polarimeter for the AmPS ring.*

An Ar-ion laser system has been selected, which can provide a 10 W continuous TEM_{00}-mode beam at $\lambda = 514.5$ nm with a divergence of 0.4 $mrad$ (full angle) and diameter of 1.8 mm.

The laser light is guided to the IR, over a total path of approximately 12 m, by a system of mirrors and lenses entering the IR through a 25 mm diameter sapphire vacuum window. Circularly polarized light is generated by the combined use of a Pockels Cell (PC) and an anti-reflection coated quarter-wave ($\lambda/4$) plate (Pl). Left-handed and right-handed polarized light is obtained by switching the high voltage on the PC. In order to minimize the degradation of the polarization during the transport of the laser light to the IR by reflections off the mirrors, the use of the PC as a half-wave ($\lambda/2$) plate is decided. The scheme of transporting either vertical or horizontal light and transforming it into circular polarized light using the $\lambda/4$ plate positioned before the entrance window to the IR is adopted. In order to prevent both the Ar-ion laser and the PC from radiation damage they will be installed at the niche of NW area of the $AmPS$ ring placed on a specially designed support structure. A chopper (CH) is mounted on the laser support structure to block the beam for background measurements.

The first fixed mirror (M_1) deflects the laser light by 90^0 and is used to steer it along the wall, in the direction of the ITH. Another deflection of 90^0 from a fixed second mirror (M_2) directs the laser beam into a system of three mirrors (RM) consisting of of two remote controlled mirrors and a third fixed mirror. This system of mirrors will be used to scan the electron beam in horizontal and vertical direction both in position and in angle. The first remote controlled mirror can be tilted in both angles and is connected to a translation stage. The laser beam leaving this mirror can be translated in one direction (horizontal) and can scan in both angles. The second remote controlled mirror is positioned in a second translation stage, producing the vertical translation of the laser beam. The laser beam leaves this mirror pointing in the vertical direction and deflects the laser light to the last mirror before the IR. This last fixed mirror is used to guide the laser light to the IR. All mirrors having diameter of 50 mm are dielectric mirrors optimized for 45^0 incidence for both 514.5 nm and 488 nm wavelengths. Mounts of fixed mirrors are adjusted by hand. DC motors are chosen for the mounts and translation stages of the remote controlled mirrors.

To facilitate the transport of the laser beam and in order to prevent the PC from high power damages a Galilean expander (E) consisting of two lenses with focal lengths of $f_1 = -2.5$ cm and $f_2 = 8.0$ cm is used before the PC. The lenses of the expander are located on the laser support structure with

coinciding focal points on the optical axis to obtain an almost parallel beam leaving the expander. The laser beam is focussed at the IR by the system of two lenses L_3 and L_4 with focal lengths of $f_3 = 200\ cm$ and $f_4 = 76\ cm$ respectively. The size of the beam at the IR can be changed by adjusting the position of lens L_3. All lenses are diffraction limited lenses and have anti-reflection coatings for both 514.5 nm and 488 nm wavelengths.

After the interaction with the electron beam the laser photons exit the IR through a second $25mm$ diameter sapphire window to a pair of locally phase-compensated dielectric fixed mirrors (M_3) with diameter of 50 mm. This pair of mirrors is used to deflect the laser light first downward and then sideways underneath the beam pipe of $AmPS$ to an analysing system consisting of a rotating Glan-Thompson prism and a power-meter.

The small fraction of the laser light transmitted through the mirrors is utilized to measure the size and monitor the position of the laser beam using $VIDICON$ camera's located before and after the IR.

4.3 Detector and background considerations

The detector (D) of the backscattered photons will be situated $\sim 10 - 12$ m downstream of the IR and should be capable of detecting γ-rays of up to 30 MeV, handling count rays of the order of few hundred of kHz and be radiation resistant. Total absorption shower counters made of dense inorganic scintillating crystals are possible candidates [7]. The use of scintillating crystals made of BaF_2 (fast component), CsI(undoped) and CeF_3 is investigated. Dense crystals with shorter radiation length and Moliere radius offer smaller detector volume.

At the beginning and in order to test and tune our optical system the use of a composite $\gamma-$ray spectrometer is decided [8]. The main detector of this spectrometer is a cylindrical BGO scintillator crystal (102 mm diameter and 100 mm long), canned in an aluminum box 0.8 mm thick, optically coupled to a Hamamatsu $R1250$ photomultiplier. The crystal is surrounded by plastic ($NE110$) cylindrical scintillator shell divided in three 120^0 sectors optically separated by an aluminum foil, 0.8 mm thick, each one seen by two $XP2312B$ photomultipliers, encased in an aluminum cylinder, 325 mm long, 420 mm external diameter and 120 mm internal diameter. This plastic scintillator shell will be used in anti-coincidence mode as a Compton suppression shield. A plastic scintillator in the front of this spectrometer will be used as the veto for the charged particles background.

Several sources of background have to be considered; sources of background photons produced by the electron beam are the synchrotron radiation and the

bremsstrahlung from the rest-gas molecules in the beam pipe. Off-momentum electrons produced by bremsstrahlung of beam particles with rest-gas molecules are the dominant source of the high energy electron background.

The main sources of synchrotron radiation in the line of sight of the detector are the two dipoles before and after the IR with bending radius of $\rho = 3.30\ m$. For these dipoles the rate of synchrotron photons with energies above $\epsilon = 100\ keV$ for 900 MeV beam energy is completely negligible. Since only photons with energy of the order of several MeV are required for the asymmetry, the synchrotron photons can be filtered out effectively with some high Z mask (copper, lead or tungsten).

Assuming a N_2 residual gas at room temperature and path length of $l_t = 300\ cm$, gas bremsstrahlung calculations indicate that in order to avoid problems with the dead-time of the detector and for a signal-to-background ratio of the order of 10 times the pressure of the residual gas should be maintained lower than $10^{-8} Torr$. Photons produced by bremsstrahlung can be measured by blocking the laser light with the Chopper and can be subtracted from the data.

A major part of the electron background can be deflected by using a sweeping magnet (Ma) in the line of sight of the detector followed collimators (not shown in the layout) that can collimate away any electrons passing the magnet.

4.4 The expected measuring time

Detailed simulations based on Monte Carlo techniques ($GEANT$) have been performed in order to study the Compton process and evaluate the expected measuring time for the longitudinal polarization, taking into account the electron beam phase space and the laser beam behaviour along the IR. Typical values of the Twiss parameters at the center of the IR used for the simulations are $\alpha_x = -1.31$, $\beta_x = 2.7\ m$ and $\alpha_y = 1.95$, $\beta_y = 7.91\ m$. The horizontal and vertical emittances for a 900 MeV energy are $\epsilon_x = 1.28 \times 10^{-7}\ rad{\cdot}m$ and $\epsilon_y = 0.32 \times 10^{-7}\ rad{\cdot}m$ respectively [9]. For a circulating electron beam with energy of $E_e = 900\ MeV$ and current $I = 75$ the simulations show that the time required for the measurement of a longitudinal beam polarization of $P_Z = 0.7$ with a statistical precision of $\Delta P_Z / P_Z = 3\%$ is less than 60 sec. In the calculations a totally circularly polarized laser beam ($S_3 = 1$) with spot diameter equal to 2.25 mm, originating from a 10 W Ar-ion laser and operating at $\lambda = 514.5\ nm$, is used. The IR of the electron and laser beams is assumed to be 1 m long.

The control of the polarimeter will be performed with a computer code developed with LabVIEW on a SUN-workstation (see Figure 3). The control of the laser and the laser beam will be done via a $GPIB$ card, which is connected to the workstation via Ethernet. The four DC-motors used for the steering of the laser beam are controlled by an $PI804$ motor controller from Physik Instumente. A resolution of 2 μm and 60 μrad can be obtained with the PI804 and the DC-motors. The PI804 has also four analog inputs, of which one will be used to read out the power-meter (JM) in the laser analysing system.

The Data Acquisition will be done with a single VME-module, designed and constructed at $NIKHEF$. The module has three analog and three digital inputs. One of the analog inputs is used for the detector signals and is connected to an 8-bit flash-ADC. The other two analog inputs can be used for the charged particle veto detector($VETO$) and the Compton Suppression Shield (CSS) and are connected to Discriminators. The three digital inputs are used as inhibit, and as messengers about the polarization state of the laser light and whether the laser light is blocked or not by the Chopper. All these digital signals are generated by the Chopper. If none of the Discriminator inputs is above threshold and if no inhibit exists, the ADC value is stored. In this way, four histograms are build inside the VME-module, representing the energy spectrum of γ-rays in the detector for left and right handed laser light, both with and without laser beam in the IR. The maximum rate at which the module can operate is $\approx 1\ MHz$. The module is read out typically every 15 sec via the $SBUS$ of the workstation. The conversion from the energy spectra to electron polarization will be done by comparing the measured asymmetry with the results of $GEANT$.

5 Summary

The laser backscattering Compton technique for electron polarimetry has been reviewed and a design procedure for a Compton-laser polarimeter for the $AmPS$ ring has been presented. The polarimeter consists of a laser system producing circularly polarized light, the laser transport and analysing system and a total absorption photon detector capable of detecting photons with energy up to several tens of MeV. The straight section between the two dipoles of the first curved section after the ITF will be used as the electron-laser IR. Monte Carlo simulations, for a continuous Ar-ion laser with $\lambda = 514.5\ nm$ operating at 10 W, predict that the measurement of the expected 70% degree of longitudinal polarization of a 75 mA circulating electron beam with energy of $900 MeV$ can be achieved, with an accuracy of 3%, in a time less than 60
